AB It was found that the dyes thymol blue, dimidium bromide, and methyl orange, which are not soluble in pure supercrit. CO2, could be conveniently solubilized in AOT water-in-CO2 reverse microemulsions with 2,2,3,3,4,4,5,5-octafluoro-1-pentanol as co-surfactant. The solubilities of the dyes in the microemulsions were measured successfully by using a UV-visible spectroscopy method newly established in our laboratory; besides that, for a given temperature, a critical micelle pressure at which formation of AOT water-in-CO2 reverse micelles starts, was determined in term of the effect of pressure on the absorption intensity of the dyes in the microemulsions. Furthermore, the micro-polarity environment of the AOT water-in-CO2 reverse microemulsions was investigated systematically according to the shift of the solvatochromic probes methyl orange and dimidium bromide with varying water content by using UV-visible spectroscopy.

AB The forward transfer kinetics of a water-soluble cationic dye (dimidium) across the planar interface from a conjugate aqueous phase to a water-in-oil (w/o) microemulsion phase (formed using the anionic surfactant Aerosol-OT) have been investigated by means of a rotating diffusion cell. By measurement of the solute flux as a function of rotation speed of the diffusion cell membrane, the influence of mass transport effects to and from the interface could be controlled and eliminated by extrapolation to infinite rotation speed. The rate of forward transfer was linearly proportional to the concentration of solute in the aqueous phase; i.e., it was not possible to saturate the aqueous side of the interface. The rate, however, was found to reach a limiting value on increasing the concentration of nano water droplets in the microemulsion phase. This is explained by a transport model in which the dye initially partitions to the aqueous side of the interface; it then enters the organic phase inside a forming water droplet. The rate of back transfer of H+ from a microemulsion droplet phase into a coexisting water phase has also been studied as a function of droplet concentration and temperature These results extend previous measurements on the same system. It is shown that enthalpy-entropy compensation effects operate for the rate-determining step. In the proposed model for defining dynamics of interface transfer from or to an aqueous phase in Winsor-II systems, the rate-determining step is the same for forward and back transfer and is concerned with droplet coalescence with the interface.

AB Disclosed is a nucleic acid hybridization assay composition for detecting the presence of absence of a target oligonucleotide or polynucleotide in a sample. The composition comprises: a solid matrix having at least one surface which is substituted with a first intercalator capable of binding dsDNA dsRNA, or DNA-RNA hybrids; a second intercalator, which may or may not comprise at least one fluorophore, said intercalator or said fluorophore each acting as either an energy donor or an energy acceptor; and an oligo- or polynucleotide probe which is specifically hybridizable with the target oligo- or polynucleotide and has directly or indirectly bound thereto, at least one lanthanide metal chelate or at least one fluorophore, each acting as either an energy donor or an energy acceptor. The method is exemplified such that the first intercalator, the phenanthridine dye M-B 3492, is used to capture the double-stranded target-probe hybrid to the surface of the slide and a second intercalator, 9-aminoacridine, is used in solution as the energy donor. Also disclosed are a method and kit for its use.

AB The efflux of [3H]choline+ from the proximal tubular lumen was measured by using the stop-flow microperfusion method. The 2-s efflux of [3H]choline+ follows kinetics with a Michaelis constant, Km = 0.18 mmol/L, maximal flux Jmax = 0.43 pmol cm-1 s-1, and a permeability term = 38.0 μm2 s-1. Replacement of Na+ by N-methyl-D-glucamine+ or Li+, or a change of luminal pH do not alter choline+ efflux. Replacement of Na+ by Cs+ inhibits 2-s choline+ (0.01 mmol/L) efflux by 22% and replacement by K+ inhibits by 49%, indicating that the elec. p.d. across the brush border membrane acts as driving force for choline+ transport. Comparing the apparent luminal inhibitory constant values for choline (apparatus Ki,l,choline+) with the chemical structure of inhibiting substrates, it was found that the inhibitory potency of amines with high pKa values, i.e. high basicity, and of quaternary ammonium compds. (tetra-Et to tetrahexylammonium) increases with their hydrophobicity in a similar manner as was observed previously against the contraluminal N1-methylnicotinamide (NMeN+) transporter and the luminal H+/organic cation (N-methyl-4-phenylpyridinium) (MPP+) exchanger. Independently of their hydrophobicity, an increase in the inhibitory potency of the homologous series of aminoquinolines against the choline+ transporter was observed with increasing pKa values, i.e. increasing basicity, as was found previously against the 2 other organic cation transporters. A third parameter influencing the interaction with the choline+ transporter is the presence of 2 amino groups with high pKa values or one amino group and a permanent pos. charge, as is documented with the 2-ring aminostyryl and rhodamine compds., as well as 3-ring aminoacridine, amminophenanthrene and cyanine compds. Thus with the aminostyryl, pyridinium+, rhodamine, phenanthridium+ and cyanine+ dyes app.Ki,l,choline+ values of between 0.01 and 0.07 mmol/L were found. A fourth parameter influencing the choline+ transporter is the presence of an OH group on the C atom next to that bearing the N atom (as in choline+) or an ester-OCOR group (acetylcholine+, butyrylcholine+) or a thioester-SCOR-group (acetylthiocholine+, butyrylthiocholine+); or an -OP(OH)2(OR) group (glycerylphosphoryl-choline+), resulting in app.Ki,l,choline+ values of 0.3-1.0 mmol/L. Thus, the substrates for the luminal choline+ transporter have general features in common with the luminal H+/organic cation exchanger and the contraluminal organic cation transporter, i.e. hydrophobicity and basicity. Addnl. parameters for interaction are an OH (or similar) group positioned a favorable distance from the N atom or a second amino/ammonium group in multi-ring compds.

AB For the two-phase titration of anionic or cationic surfactants, the most frequently used indicator is a mixed indicator system consisting of dimidium bromide and Disulphine Blue. Recently, we noticed a similarity between ethidium bromide and dimidium bromide (I). Ethidium bromide is well known as a strong mutagenic and cancerogenic agent, reacting with DNA either by intercalation or external binding. The literature shows that I reacts with DNA in a similar way. When mixing aqueous solns. of DNA and I a change in the color of the solution can be observed, as well as a strong enhancement in the fluorescence intensity. Both the literature and the exptl. findings make it very likely that I shows mutagenic and cancerogenic properties that are similar to those of ethidium bromide. This estimation is shared by the USA National Cancer Institute. Up to now, only little is known about the ways of incorporation for both dyes. Ethidium bromide shows mutagenic and cancerogenic properties when coming in contact with the mucous membrane. The author has no information whether I will be incorporated if an aqueous solution is in contact with the intact epidermis. That would be the most probable way of incorporation when carrying out a two phase titration For that reason, the appropriate safety precautions should be taken when working with I: protection gloves and goggles and addnl., when working with the solid substance, dust mask. When titrating anionic surfactants, I will be found in the aqueous phase at the end of the titration The dye should be removed from the solution by adsorption on activated charcoal or on a polymeric resin like Amberlite XAD-16. After our experience an amount of 10 g activated charcoal is sufficient for the removal of I from one liter of the aqueous phase.

AB The intervening sequence (IVS) excised from the rRNA precursor of T. thermophila is converted to a covalently closed circular RNA in the absence of proteins in vitro. This self-catalyzed cyclization reaction is inhibited by the intercalating dye methidiumpropyl·EDTA (MPE) (Hertzberg, R. P.; Dervin, P. B., 1982). The MPE-binding sites were localized by mapping the sites of MPE·Fe(II) cleavage of the IVS RNA. There are 3 major binding sites within the 414 nucleotide IVS RNA. Two of these sites coincide with the A·B and 9L·2 pairings. These are structural elements that are conserved in all group I introns and are implicated as being functionally important for splicing. It is proposed that interaction of the MPE with these sites is responsible for dye inhibition of cyclization. The reactions of MPE·Fe(II) with an RNA of known structure, tRNAPhe, and with the IVS RNA were studied as a function of temperature, ionic strength, and ethidium concentration Based on the

comparison of the reaction with these 2 RNAs, it is concluded that the dye is a very useful probe for structural regions of large RNAs, whereas it provides more limited structural information about the small, compact tRNA mol.

AB Several intercalating dyes inhibit the cation-induced condensation of λ-DNA when Co3+(NH3)6 is the condensing agent. The dyes studied are ethidium, propidium, proflavine, quinacrine, and actinomycin D. Dye-induced decondensation of intramol. condensed DNA was studied by using conditions in which Co3+(NH3)6 produces intramol. condensation without significant aggregation. Some aggregation is caused, however, during dye-induced decondensation. Dye titration curves of DNA decondensation were measured by excess light scattering to monitor decondensation and by fluorescence to monitor intercalation. All of the dyes studied act as competing cations in displacing the condensing cation Co3+(NH3)6 from the DNA. Competition occurs both in and below the transition zone for condensation. The effectiveness of a dye as a competing cation increases with its net pos. charge. Before decondensation begins, no intercalated dye can be detected, suggesting that intercalation might be incompatible with the proper helix packing needed for cation-induced DNA condensation. To test this last point, methidium-spermine was synthesized: it contains an intercalating methidium head group combined with a polyamine tail. Methidium-spermine caused λ-DNA condensation, but aggregation accompanies condensation, as has been found earlier for spermine and spermidine. Fluorescence and absorption spectra indicate that the methidium group is intercalated when the DNA is condensed, indicating that intercalating need not be incompatible with DNA condensation. The presence of aggregates among the condensed DNA mols. makes this last conclusion tentative.

AB Described herein are methods for directly labeling the 3'-phosphate end associated with photocleavage at a mismatch site. Because internal 3'-phosphate termini on DNA duplexes are also associated generally with oxidative lesions, these methods provide a general strategy also for labeling and therefore detecting the frequency of oxidative DNA lesions. Labeling using terminal transferase or nontemplated DNA polymerization is also envisaged, where using either of these activities it is possible to tag a damaged site, after removal of the 3'-phosphate, with polynucleotide tails. Such polynucleotide tails in turn can be used as primer binding sites for use in PCR. In one embodiment, a method of detecting internal 3'-phosphate termini in a nucleic acid duplex from at least one is envisaged including contacting the nucleic acid duplex with an agent to convert an internal 3'-phosphate termini to 3'-hydroxy termini, extending 3'-hydroxy termini present in the duplex by nontemplate dependent DNA polymerization, amplifying the extended product of the resulting products and identifying a nucleotide sequence-dependent feature in the resulting amplified products, where the identified feature in amplified products correlates with the presence of internal 3'-phosphate termini. Further, the converting step may include, but is not limited to, contacting the internal 3'-phosphate termini with T4-polynucleotide kinase (4-TNK) and the nucleic acid duplex containing a mismatched or damaged base. Moreover, the method includes, but is not limited to, contacting the duplex with an AP lyase (e.g., APN1), and in a related aspect, the nontemplate polymerization is carried out with TAQ polymerase, terminal deoxynucleotide transferase (TdT), or DNA polymerase Mu (Pol μ). In another related aspect, annealed nucleic acids may be obtained from more than one sample and nicks may be generated in the annealed product with an agent that cleaves mismatched or damaged nucleotides to generate internal 3'-phosphate termini. Moreover, at least one of the sample nucleic acid duplexes may include an annealed nucleic acid probe. In one aspect, the agent is a hindered intercalating compound of the formula Rh(R1)(R2)(R3)3+, where R1 and R2 are each independently aryl, heteroaryl, substituted aryl or substituted heteroaryl of 1 to 5 rings, and R3 is a group of the formula (I) wherein x and z are each independently an integer from 1 to 4 and y is an integer from 1 to 2, and R4, R5, and R6 are each independently H-, halo, HO-, H2N-, CN-, O2N-, HS-, O3S-, O3SO-, -COOH, -CONH2, RRO-, RNH-, RaRbN-, RO3S-, RO3SO-, -COOR, -CONHR, or -CONRaRb, where R, Ra, and Rb are each independently lower alkyl, cycloalkyl, lower alkenyl, lower alkynyl, or phenol, or two R4, R5, or R6 together form a fused aryl ring, wherein the compound intercalates between bases in the presence of polynucleotide damage or error and does not intercalate between bases in the absence of damage or error. In a related aspect, the agent is Δ- or Λ-Rh(bpy)2(chrysi)3+, where cleaving comprises photocleavage. In a related aspect, the mismatch is allelic and may include, but is not limited to, a single nucleotide polymorphism (SNP). In another aspect, the damage is a DNA lesion from oxidative stressor exposure, UV light exposure, or adduct formation. In one embodiment, a method of identifying mismatches in a sample nucleic acid duplex is envisaged, including producing nicks in the duplex with an agent that cleaves mismatched nucleotides to generate internal 3'-phosphate termini, extending the internal 3'-phosphate termini by nontemplate dependent DNA polymerization, amplifying the extended product, and determining a nucleotide sequence-dependent feature of the resulting amplified products, where differentiation of the feature between amplified products correlates with the presence of a mismatched base. Sensitive methods were developed to quantitate the frequency of mismatches. By labeling the site of mismatch photocleavage, either by fluorescence, radioactivity, or polymerization, quantitation of mismatch cleavage and hence the frequency of mismatches can be achieved. Herein described are methods for directly labeling the 3'-phosphate end associated with photocleavage at a mismatch site.

AB This invention provides novel polydentate selective high affinity ligands (SHALs) that can be used in a variety of applications in a manner analogous to the use of antibodies. SHALs typically comprise a multiplicity of ligands that each bind different region of the target mol. The ligands are joined directly or through a linker thereby forming a polydentate moiety that typically binds the target mol. with high selectivity and avidity.

AB This invention provides for labeling reagents, labeled targets and processes for preparing labeling reagents. The labeling reagents can take the form of cyanine dyes, xanthene dyes, porphyrin dyes, coumarin dyes or composite dyes. These labeling reagents are useful for labeling probes or targets, including nucleic acids and proteins. These reagents can be usefully applied to protein and nucleic acid probe based assays. They are also applicable to real-time detection processes.

AB This invention provides for compns. for use in real time nucleic acid detection processes. Such real time nucleic acid detection processes are carried out with energy transfer elements attached to nucleic acid primers, nucleotides, nucleic acid probes or nucleic acid binding agents. Real time nucleic acid detection allows for the qual. or quant. detection or determination of single-stranded or double-stranded nucleic acids of interest
in a sample. Other processes are provided by this invention including processes for removing a portion of a homopolymeric sequence, e.g., poly A sequence or tail, from an analyte or library of analytes. Compns. useful in carrying out such removal processes are also described and provided.

AB A conjugate of a tumor cell-targeting protein or polypeptide and a nucleic acid-targeting small mol. labeled with an Auger electron-emitting radionuclide is useful for tumor therapy. The tumor cell-targeting protein or polypeptide may be an antibody or fragment thereof, a hormone, or a growth factor. Thus, tumor-associated antigen-specific monoclonal antibody MA103 conjugated to 125I-labeled dilactitol-tyramine or 125I-labeled DTAF was internalized and processed by SK-RC-18 carcinoma cells, with retention half-lives of 104 and 52 h, resp. After lysosomal degradation of the antibody, the intracellularly released DTAF can pass through the lysosomal and nuclear membranes and bind to DNA.

AB Generally, the synthesis of activated nitrosocarbamates requires condensation of radiolabeled alkyl isocyanates with the appropriate alc. Radiolabeled alkyl isocyanates are com. unavailable and/or troublesome to synthesize; thus, an easy and economical method for preparing N-[3H]methyl-N-nitrosocarbamates suitable for use as transfer reagents via amidation of 1,2,2,2-tetrachloroethyl chloroformate with [3H]methylamine hydrochloride [affording 1,2,2,2-tetrachloroethyl N-[3H]methylcarbamate in 96% yield, sp. activity 30.1 μCi/mmol] has been developed.

AB Quant. footprinting studies involving a 139-base pair restriction fragment from pBR322 DNA, lexitropsin ligand and two different DNA cleavage agents, the enzyme DNase I and the footprinting reagent Fe(III) methidium-propyl-EDTA (Fe-MPE), are described. The autoradiog. data showed that the ligand, an analog of netropsin possessing two N-methylimidazole groups, binds to four regions on the 139-mer which are rich in GC. Anal. of the data leading to individual binding consts. for each of the four loading events on the 139-mer revealed that Fe-MPE and DNase I report the same binding consts. for the lexitropsin bound to its

interaction sequences. The fact that the data from both probes can be analyzed using a common model indicates that the DNA cleavage specificity of the probe and not its binding/cleavage mechanism is the important factor in reporting of site loading information in the footprinting experiment The study also showed that under certain conditions it is possible to gain information on the d. of ligand binding sites on carrier DNA by monitoring site loading events on the labeled fragment.

AB The interaction of a stable branched DNA mol. with an intercalative drug is probed by hydroxyl radical scission. Methidiumpropyl-EDTA·Fe(II) [MPE·Fe(II)], consisting of an intercalating ring system tethered to EDTA·Fe(II), produces the hydroxyl radicals by a Fenton reaction. The cleavage patterns of each labeled strand in a branched tetramer of 4 16-mers are compared with those of the same strands in unbranched duplex controls. Strong differences between the profiles corresponding to scission of branched and duplex DNA mols. are seen in each of the strands at low MPE/DNA ratios. A specific site in the branched structure interacts preferentially with the drug, while other regions of the mol. are protected from cleavage. At 4°, cutting at strand positions demarcating the site of enhanced affinity is observed to be .apprx.60% more efficient than at the corresponding sequence positions in the control duplex DNA mols.; the degree of protection at the second site is comparable. Cleavage in the vicinity of the preferred site occurs at residues flanking the branch point that are asym. distributed with respect to it. The reactive Fe(II) group appears to be centered within 2 residues of the branch point, and the site of preferential intercalation may be between the 2 base pairs closest to the branch point in 1 of the 4 arms. The pattern of preferential cutting at this site is eliminated in the presence of excess propidium diiodide, another intercalative drug.

OS CASREACT 109:206515
AB The synthesis and characterization of an N-methyl-N-nitrosourea (MNU) analog that is covalently linked to a methidium nucleus (I) is described. At 37° in pH 8.0 buffer I hydrolyzes via pseudo-first-order kinetics, with a calculated t1/2 = 77 min. By use of polyacrylamide sequencing gels the formation of piperidine-labile N7-methylguanine adducts from the reaction of I and MNU with 5'-32P-end-labeled DNA restriction fragments is reported. DNA methylation by I in 10 mM Tris buffer is enhanced with increasing ionic strength (50-200 mM NaCl), which contrasts to the inhibition of MNU-induced cleavage with increasing salt. In addition, I methylates all G sites equally, whereas MNU shows a clear preference for d(G)n (n ≥ 3) runs and an asym. methylation pattern within these G-rich regions. The results are discussed in terms of the delivery of the MNU moiety to the DNA target by a nonsequence-specific intercalation process and the subsequent hydrolytic generation of a nondiffusible alkylating intermediate.

AB Bulge-specific strand scission by the DNA intercalating/cleaving drugs neocarzinostatin chromophore (NCS-C), bleomycin (BLM), and methidiumpropyl-EDTA (MPE) is described. A series of 5'-32P end-labeled oligonucleotide duplexes were constituted that are identical except for the location of a bulge. In each successive duplex of the series, a bulge has been shifted stepwise up (from 3' to 5') one

strand of the duplex. Similarly, in each successive duplex of the series, sites of bulge-specific scission and protection were observed to shift in a stepwise manner. The results show that throughout the series of bulged duplexes, NCS-C causes specific scission at a site near a bulge, BLM causes specific scission at a site near a bulge, and MPE·Fe(II) causes specific scission centered around the bulge. Kn some sequences, NCS-C and BLM each cause bulge-specific scission at second sites. Further, bulged DNA shows sites of protection from NCS-C and BLM scission. The results are discussed with respect to a model of bulged DNA. It appears that specific scission at DNA bulges can be employed as a general assay for intercalation and binding orientation.

AB Complementary strand anal. of distamycin A (I)- and actinomycin D (II)-binding sites of Escherichia coli lactose operon DNA using the methidiumpropyl-EDTA-Fe(II) (III) footprinting technique was reported. Two restriction fragments, containing regions of identical sequence and 117 and 168 base pairs (bp) in length, were prepared with 3'-end 32P labeling on complementary strands and used as substrates. III cleavage inhibition patterns resulting from drug protection provided opposite-site footprints. Binding sites were localized on 50-bp sections of the restriction fragments. I binding protected 24 out of 50 bp, of which 20 (83%) were adenine-thymine pairs. The min. protected region was a 4-bp sequence, AATT. For this size sequence the binding d. (ligand bound/bp) was 0.12 or 6 mols. on the 50-bp sequence. II binding protected 22 out of 50 bp, 15 (68%) being guanine-cytosine pairs. The min. protected site was a 3-bp sequence, GTG, and the binding d. was 0.11-0.15 or .apprx.6-7 mols. on the 50-bp sequence. As predicted, the footprints were shifted 1-2 bp to the 3' side on each strand and were underprotected by 1 bp on the 5' side.

AB Acacia, agar, carbopol 934, carboxymethyl cellulose, degraded carrageen, heparin, laminarin sulfate (I), pectin, Na alginate, stearic acid, sterculia, and tragacanth were complexed with Prothidium bromide (II), 2-amino-7-(2-amino-6-methyl-4-pyrimidylamino)-9-(p-nitrophenyl)phenanthridinium 10,1'-dimethochloride (III), 2-amino-7-(2-amino-6-methyl-4-pyrimidylamino)-9-phenylphenanthridinium 10-ethomethanesulfonate 1'-methomethanesulfonate (IV), homidium bromide, isometamidium, and dimidium. The insol. complexes were prepared by slow addition of an excess of 1% solution of phenanthridinium salt in water, with stirring, to a 1% solution or gel of the complexing substance. The mixture was stirred, let stand 1 hr., then centrifuged. The precipitate was resuspended and recentrifuged. After total N analysis the precipitate was suspended in 2% hydroxyethyl cellulose. Soluble solns. were also prepared Saturated solns. of II or homidium bromide added to agar or pectin produced a color change but no precipitate The agar complexes were evaporated to dryness then redissolved in hot water. Pectin complexes were redissolved in excess of EtOH. Mice were injected subcutaneously with 0.2 or 1.0 mg. of phenanthridinium compound/kg. or the complexes. The mice were then challenged with injections of Trypanosoma congolense. Only complexes of II with I showed any marked activity in the mouse. The resuspended II-I complex was less active than the original suspension. I and degraded carrageen enhanced the activities of isometamidium and III. Coupling with I enhanced IV activity. Complexing did not change the effect of II against trypanosomiasis in cattle.
